

Shion Chen - Curriculum Vitae

Date of birth: 17 June 1989
Nationality: Japan
Address: Department of Physics and Astronomy,
University of Pennsylvania.
209 S. 33rd 19104 PA USA.
email: cshion@sas.upenn.edu
phone: +1-267-576-9389
+41-754111-3595 (CERN)

Education and Training

2014-2017

Doctor of Philosophy (Science), The University of Tokyo, Japan. JPS fellowship (DC1).

Thesis: "Search for Gluinos using Final States with One Isolated Lepton in the LHC-ATLAS Experiment".

Advisor: Sachio Komamiya, Shoji Asai.

2012-2014

Master's degree in Physics, The University of Tokyo, Japan.

Thesis: "Test of Bell's Inequality and Entanglement Measurement in Collider Experiments".

Advisor: Sachio Komamiya.

Work Experience

Post-doctoral fellow (University of Pennsylvania, Sep 2017-)

Main project: Searches for Super-symmetric particle, new lepton tagger development and the operation of the Transition Radiation Tracker in ATLAS experiment.

Advisor: Brig Williams.

Research Summary

(All the references cited in the section correspond to the numbering in the “Selected Publication” above.)

My research career has been driven by a simple desire of understanding the fundamental rules of the nature. For the five years as a graduate student in the University of Tokyo, and three years as a postdoc in University of Pennsylvania, I have pursued the fundamental theories of quantum mechanics and elementary particle physics using the platform of collider experiments. The work extends from:

- phenomenological analyses of quantum entanglement in the multi-body systems realized in collider experiments,
- development of calorimeters for the future international linear collider (ILC) project, to
- searches for supersymmetry in the ATLAS experiment in the energy frontier Large Hadron Collider (LHC) at CERN.

ATLAS experiment (2014-present)

Operation and Upgrades of the TRT Detector (2017-present)

Transition Radiation Tracker (TRT) is one of the primary tracking detectors in the ATLAS. It consists of 350,848 cylindrical 4 mm diameter straws of thin-wall proportional chamber filled with Xe/Ar-based active gas, creating ionization signals along a passage of a charged particle. While it serves as a continuous tracker, it also offers a particle identification functionality via the transition radiation radiated emitted from the polyethelene fiber/foils interspaced between the straws.

Since April 2017 I have been part of the DAQ operation crew of the TRT as a member of University of Pennsylvania, and have served as the DAQ coordinator since August 2018. The main responsibility is to ensure the smooth data-taking – from continual calibrations of low-voltage setting on front-end electronics, threshold setting, and fine delay setting, to the data flow handling from the front-end, monitoring, recovery during the operation and so on. The year of 2017 was particularly challenging for the TRT DAQ as the LHC decided to exceed the design goal in its luminosity. As having providing almost two times higher instantaneous luminosity than the nominal value, it saturated the bandwidth in many different parts of the read out path. Numerous DAQ upgrades were implemented since 2016 that includes refining the data format sent off the front-end, over-clocking the back-end electronics, improving the data compression scheme, and replacement of the transceiver cards on the back-end electronics board. I joined from the middle of the upgrades and contributed to the commissioning using the high-luminosity data-taking since the late 2017 operation.

Though the upgrades ended with a great success, we started to observe sporadic events of de-synchronization in the detector since the high-luminosity operation in Run2. While each de-synchronization only costs about 15 seconds of dead time for the auto-recovery, understanding the root cause was crucial since it can develop in the future if related to the hardware. Since becoming the DAQ coordinator, I have been leading the investigation activity. The biggest challenge was that this error was never been reproduced in any environments other than the real collisions. Still, through the in-situ hardware swapping tests and a careful log analysis, we could almost identify that the Quartz Crystal Based PLL (QPLL) chips on some patch panel boards are the most suspicious components. Numerous tests are in progress to understand the actual mechanism, and a QPLL chip replacement campaign is planned once it is proven.

The other activities during the Long Shut-down 2 (LS2; 2019-present) include the software migration, upgrade of the Trigger and Timing Controller system, the hardware spare stress-testing, and the radiation damage assessment in the TRT [8]. To the effort done during August 2018 to August 2020, the TRT-DAQ team has been awarded for the ATLAS Outstanding Achievement Award in 2021.

Searches for Electroweakino production (2015-16, 2018-present)

Supersymmetry (SUSY) in the particle physics is an elegant theoretical extension of the Standard Model (SM) by introducing new particles that have the identical quantum numbers with the SM partners except for the spins. While it is generally desirable as the solution of the hierarchy problem and the grand-unification, light electroweakinos – the SUSY partners of the SM gauge bosons and the higgs boson – are particularly well-motivated in terms of the presence of viable WIMP dark matter candidate, naturalness, consistency with the potential muon $g-2$ anomaly and so on.

First electroweakino search in ATLAS Run2 (2015-16)

Due to the small production cross-section, the production of electroweakinos were only poorly constrained by direct searches before the LHC Run2 when I joined the ATLAS. As a Ph.D student, I participated to the first chargino-neutralino pair production search in the Run2 using the 3-lepton final state and the datasets corresponding to 14.8fb^{-1} . The contribution was mainly in the area of event selection optimization and fake lepton estimation based on the vastly improved particle ID performance, as well as the software development and validation adopting to the new Run2 data format and framework. Although there was no sign of new physics found and the achieved sensitivity was still limited in that round, the analysis strategy and the software legacies were substantially inherited to the later series of the same analysis carried out with larger data statistics.

After a year leaving for my graduation and coming back to the SUSY group again as a postdoc, I set out tackling two frontiers that limited the search sensitivity: the “compressed spectra frontier” and the “high-mass” frontier:

Compressed spectra searches in the 2-/3-lepton final states (2018-present)

The compressed spectra in SUSY refers to a regime where the mass splitting between the produced SUSY particles and the lightest SUSY particle –LSP– (Δm) is small, ending up in only soft particles in the final states. Though this is exceptionally motivated regime by the thermal dark-matter relic density or naturalness, the search sensitivity faces a harsh challenge in the low- p_T electrons/muons (collectively referred to “leptons”) reconstruction versus the high fake lepton background from jets. The best exclusion limit at that time was set only up to 140 – 180 (90 – 140) GeV for wino (higgsino) production for $\Delta m < 100$ GeV, using the full-Run1 or the Run2 36.1fb^{-1} datasets. To overcome the limitation, my effort was put on improving the fake rejection by developing a machine-learning based lepton selection algorithm with particular focus on low- p_T leptons (more detailed in the next section) [7], understanding the performance, calibrating with data and introduced to the searches using the 2- or 3-lepton final states [5,6]. Having committed to the both analysis, I have contributed more to the 3-lepton search as

one of the main analyzers devising a new kinematic variable helping the discrimination, defining the event triggering strategies, polishing the event selections and advising the students in the team on various aspects of the analysis. Unfortunately again there was no evidence found beyond the SM expectation in the both analyses, the exclusion could run up to $\sim 250 - 300$ ($150 - 200$) GeV for the wino (higgsino) production with $3 \text{ GeV} < \Delta m < 100 \text{ GeV}$ using the full Run2 datasets. This corresponds to excluding signals with 5–15 times smaller cross-section with respect to the previous analyses, overwhelming the benefit of simply increasing the data statistics.

High-mass search using the final state with boosted hadronically decaying SM bosons (2018-present)

The high-mass frontier is on the other hand a regime where heavy electroweakinos are produced decaying into a substantially lighter LSP. Besides the small production cross-section, the bottleneck was identified to be the lepton requirement employed in the analyses (in fear of explosively high background otherwise) that suppresses the signal yields typically by about the branching ratio of $W \rightarrow \ell \nu$ or $Z \rightarrow \ell \ell$ ($1/15$ - $1/4$). To entirely remove this bottleneck, I have initiated a new effort targeting fully-hadronic final states exploiting the use of large-radius jets and the jet substructure “boosted boson tagging” technique”. This is the first electroweakino search in the LHC focusing on this final state, as well as one of the few analyses nowadays that target the fairly unexplored phase space since the beginning of the Run1. With a careful retuning of the boson tagging selection, for the wino (higgsino) pair production the sensitivity is expected to reach an unprecedented wino (higgsino) mass of $\sim 1 \text{ TeV}$ (800 GeV) for $\Delta m > 400 - 600 \text{ GeV}$. The analysis is also designed to target hadronically decaying $W/Z/h$ bosons inclusively, which dramatically reduces the model dependency of the search sensitivity that SUSY searches often suffers from. The results is being wrapped up and planned to be published on spring 2021.

Development and the Calibration of a new Lepton Isolation Algorithm using Machine-Learning (2018-2020)

Lepton isolation requirement is a follow-up selection suppressing fake leptons that evade the rejection by the upstream electron/muon identification. As opposed to the sophisticated multi-variate analysis techniques employed in the other fields of object reconstruction in ATLAS such as the electron ID and b -tagging, only very simple selections have been exercised in isolation, which are typically the fixed cuts in the energy sum of tracks and calorimeter clusters around the lepton candidate. In 2016, the first machine-learning based isolation was contrived in the context of $t\bar{t} + h$ search. This was a BDT taking eight input variables including number of tracks around the lepton, vectorial sum of those momenta, and b -jet likeliness calculated by the b -tagging algorithm, achiev-

ing another factor of 2-4 fake lepton reduction with 70%–90% real lepton efficiency after applying the standard isolation cut.

While this was specifically targeting high- p_T fakes from heavy-flavor hadron decays, my interest was to extend the algorithm to a broader scope, and particularly develop a “low- p_T tune” that could help the compressed SUSY analysis I was working on. The retuning was done with Shunichi Akatsuka (University of Kyoto) by re-training with a special low- p_T samples and re-optimizing the choice of input variables. This could eventually achieve $\sim 30 - 50$ (15)% more fake reduction at the same efficiency for electrons (muons).

The latter part of my effort was to promote the algorithm as the standard in ATLAS. A couple of working points were defined by junctioning the nominal and the low- p_T tune, and the efficiency measurements were done to provide the correction factors for the MC. While the data-vs-MC difference is usually more significant than the traditional isolation variables as expected, the source of the discrepancy was carefully investigated, narrowing down to a few input variables, which helped controlling the impact of the discrepancy. The BDT isolation working points became available as the collaboration-wide recommendation since 2020 [7].

Search for Gluino production using the 1-lepton final state (2015-17)

Since the discovery of higgs boson at a mass of 125 GeV, there is a dramatically increased interest in the search for gauginos since in typical minimal models, this mass naively implies a scalar top mass of several tens of TeV, beyond the reach of LHC. In the early stage of LHC Run2, the gluino search was particularly well-motivated as its production cross-section increases by a factor 4-40 due to the doubled center of mass energy with respect to Run1.

As the dissertation analysis, I participated in a gluino search focusing on the final state with exactly one lepton. My major contribution to this analysis was in the background estimation. While a careful and dedicated background modeling is crucial for a discovery-oriented analysis, it is challenging in this analysis because the signal region lies in the high energy tails of SM phase space. The background remaining after the selection are very unusual events, typically associated with many jets generated at higher-order QCD. Therefore the MC-based estimation – even assisted by the use of control regions laying in the vicinity of the signal regions – may not be always reliable. Half of the background events in the signal regions also arises from di-lepton events where one of the leptons are mis-identified or a tau lepton decays hadronically, faking as a jet. To address the estimation on this background component, I have developed a new data-driven estimation method that uses events with two leptons, replacing one of them into a missing particle or a simulated hadronically decaying tau in order to emulate the events in the signal regions. Though the achieved precision is still comparable with the nominal method, the new method significantly reduce the reliance on the MC, adding robustness to the estimation. On the other hand, I have also worked on investigating the MC mis-modeling of several main SM processes in the physics modeling group. Two results were published from the analysis with

different data statistics [4]. Unfortunately no significant deviation from the SM was observed, and an exclusion limit was set in a simplified model in which the gluino decays via a chargino. Up to a gluino mass of 1.7–2.0 TeV was excluded for LSP light than ~ 1 TeV.

Development of a databasing system for the MicroMegas detector (2014-15)

MicroMegas is a sub-detector of the New Small Wheel, aiming fast and precise measurements of muon tracks oriented to the end-caps. After a successful R&D and a proposal with TDR, it is now at the stage of fine-tuning the detailed design, including the geometry and electronics and so on. Simulation studies in accurate geometry therefore became highly important. As my authorship qualification project in ATLAS, I developed a centralized database storing the up-to-date geometrical parameters that are sufficient to define whole active area of MicroMegas in simulation.

Calorimeter developments for ILC/ILD (2012-14)

The ILC (International Linear Collider) is a (sub)TeV-scale electron-positron collider aiming precision measurements of the higgs boson, as well as probing new physics in the electroweak sector. As targeted events typically contain electroweak gauge bosons (W/Z), the precise identification, particularly through their hadronic decay mode, is crucial for many of the ILC physics programs. The requirement from physics is sub-5% energy resolution per jet, which is equivalent to 3-4 GeV resolution for di-jet invariant mass. To achieve this unprecedented benchmark, the ILD (International Large Detector) is planning to employ the particle flow algorithm (PFA) in which each jet particle is identified and the energy is measured individually. The calorimeters are the key components in this regime in which resolving the showers inside jets is key to the performance.

During the second half of my master course, I participated in the development of the silicon-tungsten electromagnetic calorimeter (SiW-ECAL) and analogue hadronic calorimeter (AHCAL) in the CALICE Collaboration for the ILD.

Commissioning of the ILD SiW-ECAL prototypes (2013)

To resolve individual clusters inside jets, a highly granular spatial segmentation is required for ILD calorimeters. A silicon-tungsten sampling calorimeter is the one of the leading candidate technology for the ILD electromagnetic calorimeter where the silicon sensor layers are segmented into 5-10mm pixels. The first generation prototype, with about 10000 readout channels, was developed in the CALICE collaboration in 2006, and regularly tested in test beam experiments since then.

I analyzed the data collected at a test beam in FNAL in 2011, and verified that the basic performance (linearity, energy resolution, spatial resolution of cluster centroid etc.) fulfills the requirements. The second-generation prototype was designed as a test for a fully integrated detector including data acquisition system with newly developed readout ASICs (SKIROC2) [3].

Performance study of the PFA/ILD SiW-ECAL in a realistic detector setup (2012-14)

While simulation studies have shown that PFA with the ideal ILD detector model performs very successfully, there are still a number of industrial challenges to achieve the specification of an ideal detector with ideal digitization, for instance the increased dead volume due to realistic PCB thickness or the protection frames around silicon sensor cells (“guard ring”) which did not present in the baseline simulation model. I performed a set of studies on the impact of such effects due to the features of a realistic detector on physics performance. The jet energy scale and resolution were parametrized as a function of guard ring width, PCB thickness, fraction of dead pixels/ASICs, noise rate, and cross-talk rate between channels etc., and closely evaluated the dependency using simulation. The results illustrate that the performance of PFA even under the most pessimistic conditions is still excellent and robust [2], and also provides primary guidance for the definition of manufacturing requirements in the future.

Commissioning of the power-pulsing scheme for ILD AHCAL (2013)

Due to the beam structure in ILC (1ms of beam train every 200ms), a power cycling scheme called “power-pulsing” has been proposed to minimize the power consumption. In this scheme, power supply is synchronized with beams so that power is turned off when collisions do not take place. The DESY FLC group has been working on implementing this into AHCAL electronics. In 2013, I was involved in the commissioning using the test board for my summer student project at DESY.

The test board consists of a detector layer instrumented with $30\text{mm} \times 30\text{mm}$ square cells of plastic scintillator each equipped with a SiPM, and the readout layer with front-end electronics interfaced to the SiPM attached on the back. Tests were performed with injection of LED pulses, to investigate the physical response of the detector and the readout cycle in a realistic setup. Unstable behavior was generally observed shortly after turning on the electronics, for example worse resolution in single photon spectra from the SiPM and a drop in the gain. I evaluated the impact on data quality and measured the time evolution of the behavior, as well as studying the optimal board configuration for mitigating these effects.

Testing local-reality in collider experiments (2012-14)

While quantum mechanics (QM) is without doubt a very successful theoretical framework in describing the microscopic scale of physics, it is seemingly still on a non-trivial basis; whether observables are intrinsically undeterministic (“non-realism”) and whether the nature can be “non-local”. Such counter-intuitiveness was in fact had been considered a problem as articulated by the “EPR paradox”. This has been formulated as a physical problem via Bell’s inequality, and its violation observed in 1970-80s using entangled photon pairs eloquently indicated the experimental exclusion of local-realism. Although loopholes were pointed out in the early experiments, these have been dramatically improved thanks to the rapid evolution of photon sensing and the laser technology. It is finally the time we have to say goodbye to our intuitive – local and deterministic – picture of physics.

So anything still left to do in the post-EPR era? Yes – experiments in the other kind of systems are also interesting in terms of testing the universality of quantum nature. In particular, tests of Bell’s inequality using entangled massive particles are non-trivial as they are more ‘classical’ due to its shorter Compton wavelength. Few experiments were done so far, due to the technical difficulties of preparing and measuring the entangled states. High energy colliders have been anticipated as a new platform, since spin-entangled particle pairs can be easily prepared via a variety of processes with large statistics, in a wide range of energies from a few GeV to an order of a few 100 GeV, and with various types of interaction involved. The spin can be then measured by reconstructing the decay angle distribution of the decay products. The down-side is the nature of indirect measurements i.e. the spin can only be measured through its decay to which observer’s free-will cannot intervene (“free-will loophole”). Nevertheless it can open up a various available channels even though at some cost of rigorousness.

My master thesis project was to study the feasibility i.e. what particle systems are ideal and how statistically significant those channels can be. This compelled reformulating Bell’s inequality for the particular problem, and we obtained a brief metric for the level of violation [1]. Checking in the past and ongoing experiments, charmonium decays ($J/\psi, \eta_c^0, \chi_c^0 \rightarrow \Lambda \bar{\Lambda}$) in BES3, the di-tau production at Belle ($ee \rightarrow \tau\tau$) and $H \rightarrow \tau\tau$ in ILC are statistically promising with $2 - 3\sigma$ level of significance. Finally, the effect of detector resolution and the background contamination is discussed along with the possible loopholes arising from the setup.
